The article by Thorne Lay and Hiroo Kanamori, "Measured energy in Japan," is an excellent example of the high quality of the journal's content. The authors provide a clear and concise summary of the seismic energy released during the 1994 Chiba earthquake, and their calculations are well-documented and easy to follow. The article is a valuable contribution to the field of seismology and is highly recommended for reading.

By the act of hitting a ball with a bat, one calculates the force energy to deliver the ball to its new location, but one must also take into account that the ball extended its energy release to that location which became struck by the ball as its momentum ceased and passed energy to the struck item. Therefore the parameters of the damage extend into the future when the received energy to that pushed upon, later becomes released in a new event. Perhaps calculations of one added that in, while another's calculations did not. E.M.C.

(Received 14 February 2014; accepted 4 April 2014; published online 17 April 2014)

We report on an experimental study on the spin-waves relaxation rate in two series of nanodisks of diameter $\phi = 300, 500$, and 700 nm, patterned out of two systems: a 20 nm thick yttrium iron garnet (YIG) film grown by pulsed laser deposition either bare or covered by 13 nm of Pt. Using a magnetic resonance force microscope, we measure precisely the ferromagnetic resonance linewidth of each individual YIG and YIG/Pt nanodisks. We find that the linewidth in the nanostructure is sensibly smaller than the one measured in the extended film. Analysis of the frequency dependence of the spectral linewidth indicates that the improvement is principally due to the suppression of the inhomogeneous part of the broadening due to geometrical confinement, suggesting that only the homogeneous broadening contributes to the linewidth of the nanostructure. For the bare YIG nano-disks, the broadening is associated to a damping constant $\alpha = 4 \times 10^{-4}$. A threefold increase of the linewidth is observed for the series with Pt cap layer, attributed to the spin pumping effect. The measured enhancement allows to extract the spin mixing conductance found to be $G_{\uparrow\downarrow} = 1.55 \times 10^{14} \Omega^{-1} \text{m}^{-2}$ for our YIG(20nm)/Pt interface, thus opening large opportunities for the design of YIG based nanostructures with optimized magnetic losses. © 2014 AIP Publishing LLC. [<http://dx.doi.org/10.1063/1.4871516>]

Yttrium iron garnet ($\text{Y}_3\text{Fe}_5\text{O}_{12}$), commonly referred as YIG, is the champion material for magneto-optical applications as it holds the highest figure of merit in terms of low propagation loss. It is widely used in high-end microwave and optical-communication devices such as filters, tunable oscillators, or non-reciprocal devices. It is also the material of choice for magnonics,¹ which aims at using spin-waves (SWs) (or their quanta magnons) to carry and process information. The development of this emerging field is presently limited by the damping constant of SW. Recently, it was proposed that spin-current transfer generated by spin Hall effect from an adjacent layer can partially or even fully compensate the intrinsic losses of the traveling SW beyond the natural decay time. The achievement of damping compensation by pure spin current in 1.3 μm thick YIG covered by Pt was reported by Kajiwarra *et al.*,² although attempts to reproduce the results have so far failed.^{3,4} Given that the spin-orbit torque is purely interfacial in such hybrid system, it is crucial to work with nanometer-thick films of epitaxial YIG. Primarily, because the interface spin-current transfer scales inversely with the YIG thickness.⁵ Second, because it permits nano-patterning of the YIG and thus the engineering of the SW spectra through spatial confinement.⁶⁻⁸ There is, however, no report yet⁹ on the measurement of the dynamical properties on submicron size nanostructure patterned out of YIG ultrathin films.

Benefiting from our recent progress in the growth of very high quality YIG films by pulsed laser deposition

(PLD),⁴ here we will demonstrate that these ultra-thin YIG films (thicknesses ranging from 20 to 4 nm) can be reliably nano-patterned into sub-micron size nano-disks. In the following, we will perform a comparative study of the linewidth on these nanostructures. We will analyze the different contributions to the damping by separating the homogeneous from the inhomogeneous broadening and quantify the spin-pumping contribution when an adjacent metallic layer is added. We will also evaluate the consequences of the damages produced by the lithographic process on the dynamical response of these devices. It will be shown that the different alterations produced by chemical solvent, heat treatment, amorphization and redeposition of foreign elements during the lithography, edge roughness, etc., do not produce any increase to the linewidth, offering great hope for incorporation of these YIG films in magnonics.

The 20 nm thick YIG has been grown by PLD on a (111) $\text{Gd}_3\text{Ga}_5\text{O}_{12}$ substrate following the preparation described in Ref. 4. A 13 nm thick Pt layer was then deposited by sputtering on half of the YIG surface. One slab of 1×5 mm was cut to perform standard magnetic hysteresis and ferromagnetic resonance (FMR) measurements. The measured magnetic parameters of the bare YIG film are summarized in Table I. On the remaining piece, a series of YIG

FIG. 1. Optical image of the YIG disks, with (red) and without (blue) Pt on top, placed below a microwave antenna. The direction of the microwave magnetic field is indicated by a blue arrow. The external bias magnetic field is oriented perpendicularly to the surface.

nanodisks have been subsequently patterned using standard electron lithography and dry ion etching. After the YIG lithography, an insulating layer of 50 nm SiO₂ was deposited on the whole surface and a 150 nm thick and 5 μ m wide microwave Au-antenna was deposited on top. Fig. 1 shows an optical image of the sample and the antenna pattern. The series of decreasing diameters bare YIG nanodisks are placed on the left. The spacing between the disks is 3 μ m. The series of disks on the right side mirrors the first one and have a 13 nm Pt layer on top. Here, we concentrate on the disks enclosed in the rectangular area, with nominal diameter $\phi = 700, 500$, and 300 nm.

To measure the FMR-spectra of the nanodisks buried under the microwave antenna, we use a ferro-magnetic resonance force microscope (f-MRFM).¹¹ It is based on measuring the deflection of a cantilever with a magnetic Fe particle of about 800 nm diameter affixed to the tip. The tip magnetic dipole moment senses the stray field produced by the perpendicular component M_z of the magnetization of the magnetic nanodisks, which is modulated by the exciting microwave power at the mechanical frequency of the cantilever.

TABLE II. Comparative table of the measured and predicted (analytical and Spin flow simulations)¹⁰ resonance values for the SW modes. These predictions are uncorrected by the additional stray field of the f-MRFM probe. The last column displays the SWs eigenvalues obtained by adjusting both the diameter of the disks (respectively, $\phi = 700, 520$, and 380 nm) and the probe sample separation (respectively, $h = 3.0, 2.0$, and 1.5 μ m). The SWs are labeled by their azimuthal and radial number (ℓ, n).¹⁰

ϕ (nm)	Mode	f_{exp} (GHz)	Simu.	Analyt.	Fit

In Fig. 2, we show f-MRFM spectra recorded for different diameters (by row) on both the YIG and YIG|Pt nanodisks (by column). The spectra correspond to the spin-wave eigenmodes of the disks biased by a perpendicular magnetic field $H_0 = 4.99$ kOe. The largest peak at lowest frequency stems from the lowest energy FMR-mode, the so-called uniform mode. The smaller peaks at higher energy correspond to higher order modes.¹² The splitting corresponds to the quantization of the SW wavenumber $\propto n\pi/\phi$ (where n being an integer) in the radial direction.¹¹ One can thus infer from the peak separation the lateral size of the disk. Using the literature^{13,14} value for the YIG exchange length $\Lambda_{\text{ex}} = 15$ nm, a fit of the peak separation leads to an effective confinement of, respectively, 700, 520, 380 nm for our 3 disks, assuming total pinning at the disk edge (see Table II). This is in very good agreement with nominal sizes targeted by the patterning. Differences with the nominal value are due both to imperfection of the lithographic process and the dipolar pinning condition,¹⁵ which scales as the aspect ratio. Confining a spin wave in a smaller volume leads also to an

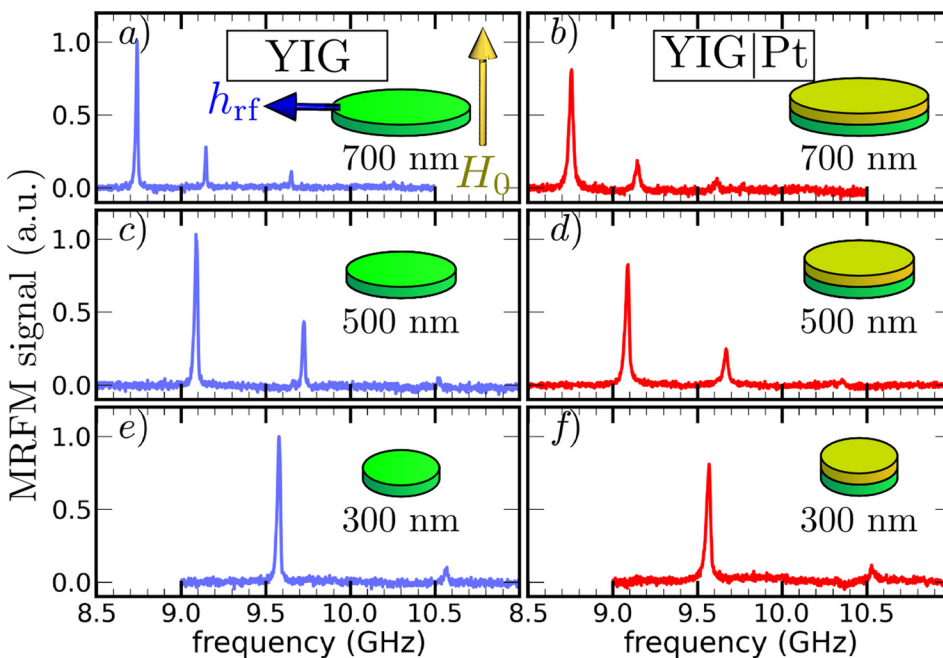

FIG. 2. Mechanical-FMR spectra at $H_0 = 4.99$ kOe of the 700, 500, and 300 nm diameter YIG disks arranged in rows by decreasing lateral size. The spectra of the pure YIG disks are shown in the left column (blue), while the ones covered with 13 nm of Pt are shown in the right column (red).

overall increase of the exchange and self-dipolar energy, and thus a shift of the fundamental mode with increasing energy. We have checked that the position of the peak is compatible with the magnetic parameters shown in Table I assuming that the center of the probe is approached from 3.0 to 1.5 μm when moved from the largest to the smallest disk.

From the comparative measurements presented in Fig. 2, we see that the peak position is not altered by the addition of the Pt layer on top of the YIG disk whereas its linewidth is clearly increased. To emphasize this result, Fig. 3 shows the linear f-MRFM spectra of the 700 nm bare YIG (b, blue dots) and of the YIG|Pt (c, red dots) disks. For comparison, the spectrum measured on the extended YIG thin film is shown in (a, black). It was recorded with a transmission line Au-antenna of 500 μm width and an in-plane external field oriented perpendicularly to the exciting microwave field, similar to the configuration used in Ref. 3.

A first striking result of Fig. 3 is obtained by comparing the spectra measured in extended film (a) and the nanostructure (b) for the bare YIG: the nanopatterning *improves* the linewidth.⁷ One can observe that, while the lineshape of the resonance has a Lorentzian shape in the nanostructure (continuous line), the peak shape is asymmetric in the YIG film. We attribute it to inhomogeneous broadening. This is confirmed by performing experiments on different slabs of the reference film, which actually yield different lineshapes

(not shown). The usual method of separating the homogeneous contribution from the inhomogeneous one is to study the frequency dependence of the half-linewidth $\Delta f/2$. The slope gives α , the Gilbert damping constant, while the zero frequency intercept gives the inhomogeneous contribution. In Fig. 3(d), we have thus plotted the full-linewidth Δf of the extended reference film at different frequencies using the same color as in Fig. 3(a). The linewidth varies almost linearly with the frequency. We extract from the slope the damping 4×10^{-4} , while the intercept at zero frequency indicates the amount of inhomogeneity of the resonance: $\Delta f = 2.5$ MHz (or $\Delta H = 1$ Oe).

On the same Fig. 3(d), we show using red dots the frequency dependence of the linewidth of the YIG|Pt nanostructure. The fit of the slope yields $\alpha_{\text{YIG|Pt}} = 13 \times 10^{-4}$. The striking feature is that a linear fit now intercepts with the origin of coordinates. It means that the linewidth measured in the nanostructures directly yields the homogeneous contribution. For the bare YIG nanodisk, it was only possible to reliably extract the linear linewidth at one point at 8.2 GHz (blue dot). Interestingly, enough the slope of the straight line from this point to the origin is exactly that of the line fitted to the extended film data. We speculate by analogy to the Pt/YIG case that the linewidth in the YIG nanostructure is purely homogeneous in nature, while the intrinsic part of the damping has been unaffected by the lithographic process.

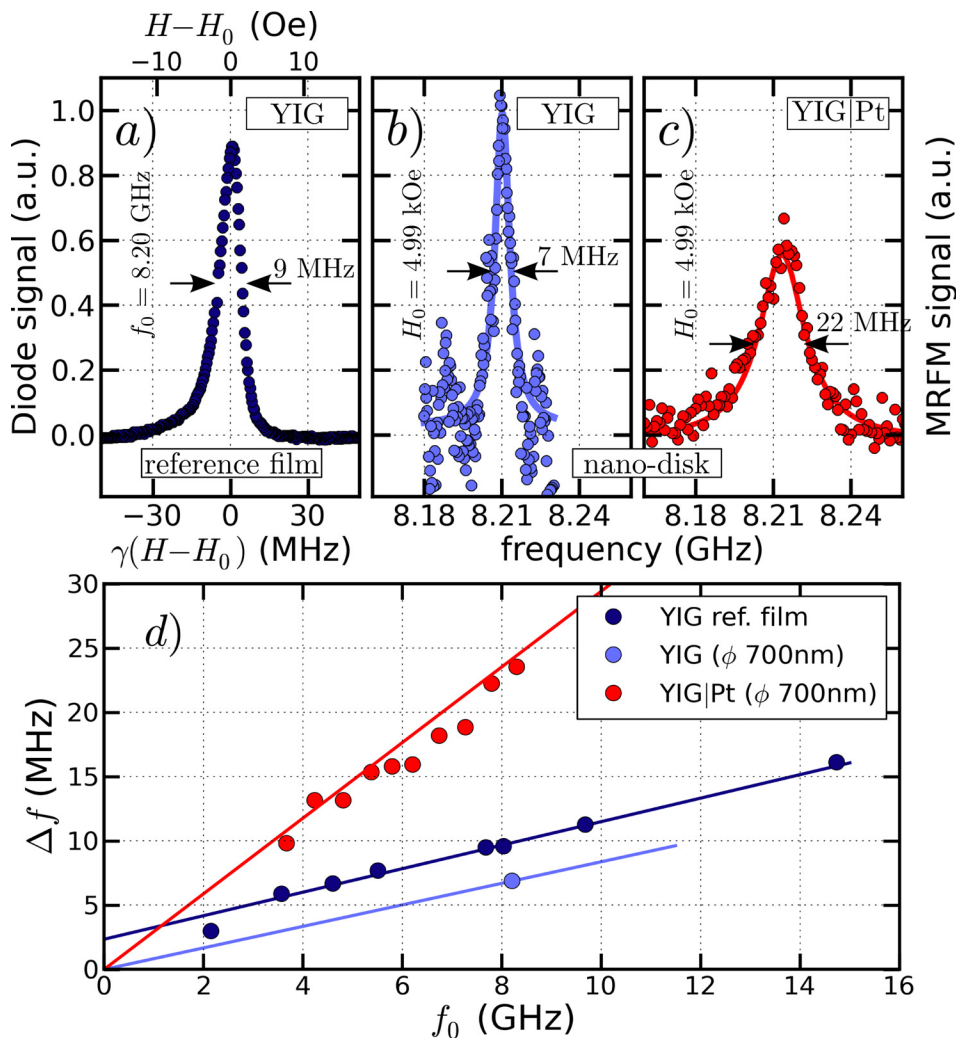

FIG. 3. (a) Low-power spectrum of the reference YIG film recorded at $f_0 = 8.2$ GHz. Lineshape of the uniform mode measured at $H_0 = 4.99$ kOe on the 700 nm disk bare (b, blue circles) and with (c, red circles) Pt. (d) Dependence of the linewidth on the resonance frequency.

In Fig. 3, we also see that the linewidth of the 700 nm YIG|Pt disk is 22 MHz (c), i.e., about three times wider than that of the 700 nm YIG disk, which is 7 MHz (b). The influence of an adjacent Pt layer is shown to increase the damping three-fold. We attribute this increase exclusively^{16,20–22} to spin-pumping effect.¹⁷ The characteristic parameter for the efficiency of spin transfer across the interface and the accompanying increase of damping in YIG is the spin mixing conductance $G_{\uparrow\downarrow}$. One can directly evaluate the increase of damping induced by the presence of the Pt layer. As we find $\alpha_{\text{YIG}} = 4 \times 10^{-4}$ and $\alpha_{\text{YIG|Pt}} = 13 \times 10^{-4}$, we deduce a large spin-pumping contribution $\alpha_{\text{sp}} = 9 \times 10^{-4}$ that adds to the intrinsic damping: $\alpha_{\text{YIG|Pt}} = \alpha_{\text{YIG}} + \alpha_{\text{sp}}$. From this, one can calculate the spin mixing conductance according to the following equation:¹⁸

$$G_{\uparrow\downarrow} = \alpha_{\text{sp}} \frac{4\pi M_S t}{g\mu_B} G_0, \quad (1)$$

where $t = 20$ nm is the YIG thickness, g is the electron Landé factor, μ_B is the Bohr magneton, and $G_0 = 2e^2/h$ is the quantum of conductance. This corresponds to: $G_{\uparrow\downarrow} = 1.55 \times 10^{14} \Omega^{-1} \text{m}^{-2}$ for our YIG|Pt interface.

In summary, we have conducted a study of spin wave spectra of individual submicron YIG and YIG|Pt disks. We find that the lithography process does not broaden the linewidth and on the contrary, the linewidth decreases compared to the extended film. The influence of an adjacent Pt layer on the YIG through the spin pumping effect is investigated and quantified to increase the damping 3 fold. As a non-zero spin mixing conductance is determined, these experiments pave the way for observation of inverse spin Hall effects in a YIG|Pt nanodisk accessing its individual spin wave modes. Most importantly, thanks to the small volume and purely intrinsic damping of the YIG sample, we will address in future studies the influence of direct spin Hall effect on the linewidth of these YIG nano-disks as it was demonstrated in all-metallic NiFe/Pt dots.¹⁹

- ¹⁶One FMR study²⁰ has found that part of the enhancement may originate from the ferromagnetic ordering in the Pt atomic layers adjacent to the YIG interface and whose signature is a frequency shift of the resonance. We do not observe this shift in our films (i.e., absence of induced magnetization in our Pt), suggesting that the effect may be sample dependent. This is coherent with more direct measurements of the induced moment in the Pt which give contradictory results.^{21,22}
